**ABSTRACT**

Tomato is classified as a functional food due to its high content of vitamins, lycopene, phenolics, flavonoids and fibers. Nonetheless, tomatoes are very sensitive soft-textured fruit, for which improper handling may reduce final product quality. The flavors of fresh, commercially produced fruits and vegetables, such as tomato, are generally considered poor by the consumer. Consequently, it is important to maintain horticultural product quality to offer more pleasant flavors and, beyond that, prevent food losses. Some mechanical forces, such as compression, can bruise tomatoes. However, such forces may not cause externally perceptible injuries. Despite this, internal bruises and cell damage still can change fruit physiology, increasing respiration and accelerating ethylene production. Therefore, it may be necessary to adopt different technologies depending on the postharvest management that the fruit received. A study of ethylene and carbon dioxide produced by tomatoes simulating different such management practices, resulting in occurrence of mechanical damages, can provide great value to development of technologies such as new packages, coatings, machinery and implements. The aim of this paper was to subject tomatoes to mechanical damage caused by compression that resulted in no perceptible injury, and measure the resulting changes in the respiration rate and ethylene production patterns. Tomatoes were subjected to compression using different loads: 0, 1, 5 and 10 kg. Ethylene and carbon dioxide production were evaluated after 1 hour and during 7 days of storage. An increase in ethylene production was observed for all treatments, while carbon dioxide production increased on only the first day of storage. Mechanical damages were responsible for increasing tomato ethylene production during the entire postharvest life and the respiration immediately after the application of treatments.

39 **RESUMO**

40 **Avaliação preliminar de alterações fisiológicas em tomates com danos**  
41 **mecânicos para o desenvolvimento de tecnologias de pós-colheita.**

42 Tomates são classificados como um alimento funcional, devido ao seu alto teor de  
43 vitaminas, licopeno, fenólicos, flavonóides e fibras. No entanto, são frutos sensíveis e  
44 de textura macia, onde o manuseio indevido pode reduzir a qualidade do produto final.  
45 Frutas e hortaliças comercializados frescos, como o tomate, são geralmente  
46 considerados pobres de sabor pelo consumidor. Por isto, é importante manter os  
47 produtos hortícolas com qualidade para oferecer sabores mais agradáveis e, além disso,  
48 evitar as perdas de alimentos. Algumas forças mecânicas, como a compressão, pode  
49 danificar os tomates sem causar lesões perceptíveis. Apesar disso, danos internos e  
50 celulares ainda podem alterar a fisiologia do fruto, aumentando a respiração e  
51 acelerando a produção de etileno. Diante disso, pode ser necessário a adoção de  
52 diferentes tecnologias dependentes do manuseio pós-colheita que os frutos receberam.  
53 O estudo da produção de etileno e dióxido de carbono por tomates simulando diferentes  
54 manejos, como a ocorrência de danos mecânicos, pode ter grande valor para tecnologias  
55 em desenvolvimento, tais como novas embalagens, coberturas, máquinas e  
56 implementos. O objetivo deste trabalho foi submeter tomates a danos mecânicos não  
57 perceptíveis causados por compressão, e verificar as mudanças nos padrões de produção  
58 e taxa de respiração de etileno. Tomates foram submetidos a compressão utilizando  
59 diferentes cargas: 0, 1, 5 e 10 kg. A produção de etileno e dióxido de carbono foi  
60 avaliada após uma hora e ao longo de sete dias de armazenamento. Observou-se uma  
61 mudança no padrão de produção de etileno em todos os tratamentos, enquanto a  
62 produção de dióxido de carbono foi mais afetada no primeiro dia. Danos mecânicos  
63 foram responsáveis pelo aumento da produção de etileno tomates ao longo de toda a  
64 vida pós-colheita, e da respiração imediatamente após a aplicação dos tratamentos.

## 69 INTRODUCTION

70 Tomato (*Lycopersicon esculentum* Mill) world production was estimated at 145.8  
71 million tons in 2010, distributed throughout the world (FAOSTAT, 2012). Brazil is  
72 currently the 9th largest producer of tomatoes and produced 3.7 million tons in 2010,  
73 24% more than 10 years ago (FAOSTAT, 2012). Soft fruits, such as tomatoes, are very  
74 sensitive to improper handling, storage and transport conditions. Therefore, proper pre  
75 and postharvest handling are critical for obtaining their highest quality, a requirement  
76 for successful fruit marketing (Yahia et al., 2005). Mechanical damage in tomatoes is  
77 the most common and severe defect in this crop; it has great economic consequences,  
78 mainly due to negative changes in sensory attributes and internal breakdown reactions  
79 (Martinez et al., 2004). Bruising injuries, which leave the skin intact and may not be  
80 visible externally may cause increases in respiration and ethylene production (FAO,  
81 2011). Physiological disorders caused by mechanical damages can modify flavor and  
82 aroma of tomatoes, reducing the potential acceptance of this product (Moretti &  
83 Sargent, 2000). Moretti et al. (1997) conducted a sensory analysis test to study  
84 consumer acceptability of tomato fruit with internal bruising. The results suggested that  
85 tomato flavor compounds alterations could be associated with mechanical injuries such  
86 as internal bruising. This provides evidence of the need to avoid mechanical damage,  
87 and to develop and adopt appropriate technologies depending on changes in physiology  
88 caused by postharvest handling. This work aimed to subject tomatoes to mechanical  
89 damage caused by compression that resulted in no perceptible injury and verify changes  
90 in ethylene production and respiration rate patterns.

## 91 MATERIAL AND METHODS

92 The experiment was carried out in the Horticultural Sciences Department - University of  
93 Florida. Plant material was cultivar Tasti-Lee<sup>®</sup> tomatoes produced in the state of  
94 Florida- USA. Tomatoes were selected at stage 2 of maturation (breakers) with no pests,  
95 diseases or any severe or mild defects. Tomatoes were exposed to compression loads of  
96 0 (control), 1, 5, 10 or 20 kg for 10 seconds with a TA.HD.Plus texturometer (Atta-Aly  
97 El & Awady, 1995). The fruit were stored in a cold room with controlled temperature ( $\pm$   
98 22°C) and relative humidity (60%). For evaluations, tomatoes were placed in 500 mL  
99 glass jars and, after 1 hour, a gas sample of 1 ml was withdrawn for ethylene and CO<sub>2</sub>

Anais... Aracaju-SE.

analysis using a gas chromatograph - Varian CP3800. Analyses were carried out in 0 (1 h after treatments applications), 1, 4 and 7 days after harvest.

## **RESULTS AND DISCUSSION**

It was verified that an increase in ethylene production occurred for all treatments 1 h after tomatoes were subjected to compression forces (Fig 1). Tomatoes subjected to the 1-kg load treatment was able to recover and produce ethylene in the same pattern as the control, and remained so throughout storage, not demonstrating significant differences from the control. This result is evidence that when the compression force received by the fruit was relatively low, the tomatoes could recovery a normal ethylene production compared to the control. Therefore, they may have their postharvest longevity less impaired by the occurrence of mechanical damages by compression. The effect of ethylene in postharvest ripening is widely known and the increase of its biosynthesis until concentrations that stimulate this process are reached characterizes the transition between development and senescence stages for vegetables (Chitarra & Chitarra, 2005). The other treatments exhibited increased ethylene production following compression that did not returned to levels displayed by the control. The ethylene production by the 5-kg and 10-kg load treatments increased and the production returned to control levels only by 7 days of storage. However, such recovery after 7 days does not represent an advantage, since during those days the ethylene production increased in some cases by more than 67% as could be noticed on day 0 for the 10-kg load treatment, which was accompanied by acceleration of fruit ripening (Fig 1). The ethylene production by the 20-kg treatment was never at any time equivalent to the control patterns, generating 56, 29, 18 and 16% more ethylene after 0, 1, 4 and 7 days . These results indicate that despite increased ethylene production on the first day, the load of 1 kg of compression would be the maximum tolerable in terms of ethylene production in this test. Above that, the production increased significantly and did not return to the control levels. Ethylene production increases tomato ripening processes logarithmically and reducing postharvest life of this product. Studies on a wide variety of fruits and vegetables have shown that any ethylene level is considered deleterious and can reduce postharvest life (Wills & Warton, 2004).

Spricigo, P.C.; Corrêa, D.S.; Ferreira, M.D.; Brecht, J.K. 2015. **Preliminary evaluation of physiological changes in tomatoes with mechanical damage related to development of postharvest technologies.** In: Congresso Brasileiro de Processamento mínimo e Pós-colheita de frutas, flores e hortaliças, 001. Anais... Aracaju-SE.

132 Carbon dioxide production (Fig 2) was increased by mechanical damage only on day 0  
133 of the experiment. Control, 1-kg and 5-kg loads behaved similarly, while larger loads  
134 increased respiration significantly in relation to the control. However, it was observed  
135 that respiration rates were not consistently affected by compression beyond the first day.  
136 Accordingly, it was observed that mechanical damage caused by compression of more  
137 than 1 kg applied for 10 seconds was responsible for increasing the tomatoes ethylene  
138 production along all of its postharvest life and responsible for increasing the respiration  
139 only immediately after the application of treatments. Thus, it is recommended to take  
140 into consideration the potential for postharvest quality losses in relation to management  
141 of these fruit, especially when developing processes and technology to be applied after  
142 harvesting. In this perspective, some simple solutions can be adopted to prevent  
143 excessive damages of tomatoes until their arrival to consumers, since ripening and  
144 softening are key attributes that contribute to the vegetables perishability (Kader &  
145 Rolle, 2004). The adoption of methods to avoid excessive ethylene production and  
146 respiration can positively influence tomato conservation. The use of suitable packages  
147 and coatings to protect fruits during transportation and marketing can be a way to  
148 conserve fruit quality.
